Abstract

Relating the effective Lorentz violation coefficients for composite particles to the coefficients for their constituent fields is a challenging problem. We calculate the Lorentz violation coefficients relevant to the dynamics of an α -particle in terms of proton and neutron coefficients. The α -particle coefficients would lead to anisotropies in the α -decays of nuclei, and because the decay process involves quantum tunneling, the effects of any Lorentz violations could be exponentially enhanced.

1 Introduction

At present, there exists a great deal of interest in the possibility that Lorentz and CPT invariance may not be exact in nature. If the fundamental physical laws do not respect these symmetries, then we could expect to see evidence of Lorentz and CPT violations even in the effective theory that governs conventional low-energy phenomena. If small violations of these symmetries were discovered, this would provide a critically important piece of information about the fundamental structure of physics and a clue to what other new effects we could expect to see. There is a parameterization of Lorentz and CPT violations in low-energy effective field theory, known as the standard model extension (SME), which contains possible Lorentz- and CPT-violating corrections to the standard model [1, 2] and general relativity [3]. Both the renormalizability [4, 5] and stability [6] of the SME have been carefully examined.

The SME provides a useful framework for interpreting experimental tests of Lorentz and CPT symmetry. Sensitive searches for Lorentz violation have included studies of matter-antimatter asymmetries for trapped charged particles [13, 14, 15] and bound state systems [16, 17], determinations of muon properties [18, 19], analyses of the behavior of spin-polarized matter [20, 21], frequency standard comparisons [22, 23, 24, 25], Michelson-Morley experiments with cryogenic resonators [26, 27, 28], Doppler effect measurements [29, 30], measurements of neutral mesons [31, 32, 33, 34, 35, 36], polarization measurements on the light from distant galaxies [37, 38, 39, 40], high-energy astrophysical tests [41, 42, 43, 44] and others. The results of these experiments set bounds on various SME coefficients. Up-to-date information about bounds on the SME coefficients may be found in [45]; at the present time, many of the SME coefficients are quite strongly constrained, but many others are not.

There are many systems and reaction processes that could potentially be used to set further bounds on the SME's coefficients for Lorentz violation. We shall consider a particular system—the helium nucleus, or α -particle—because of the insights it provides into the general properties of Lorentz-violating physics.

One challenging problem in the study of Lorentz violation is understanding Lorentz violation for composite particles. The fundamental fields in the SME are the gauge fields, leptons, quarks, and the Higgs. However, bounds on Lorentz violation are usually formulated in terms of bounds on SME coefficients for hadrons, rather than the more fundamental quark and gluon coefficients. The reason for this is obvious; hadrons are the physical excitation of the strongly interacting fields. However, they have a nontrivial structure, and the relationship between the quark, gluon, and hadron coefficients is not entirely clear.

There are very precise bounds on many Lorentz violation coefficients for the proton and neutron. However, most measurements of these coefficients are made not on free nucleons but on more complicated nuclei. Some model must be used to relate the possible effects of Lorentz violation in the nuclear system to the coefficients for individual nucleons. This is a

simpler problem than relating hadron coefficients to the coefficients for subnuclear partons. It is often reasonable to take a simplified model, such as the Schmidt model [46], which assigns all the angular momentum of nucleus to a single unpaired nucleon constituent. However, this model obviously entails a great deal of idealization, and we would like to understand the nature of Lorentz violation in nuclei and other composite particles more fully.

In this paper, we shall consider one of the simplest composite particles: the helium nucleus, containing two protons and two neutrons. The simple closed shell structure of this nucleus ensures that many spin-dependent coefficients must vanish. Yet there is still some nontrivial structure which we shall uncover. We shall then examine the possible impact of Lorentz violation on the α -decays of nuclei.

There are several motivations for this work. First, it presents a new calculation of the effective Lorentz violation coefficients for a composite particle, in terms of the coefficients for its constituents. Second, it examines how the effects of Lorentz violation can affect the intrinsically quantum mechanical phenomenon of tunneling. Finally, it suggests a new method for placing laboratory bounds on a number of Lorentz violation coefficients for protons and neutrons. Although the likely constraints are not particularly tight, this method offers a way to constrain several coefficients that have not previously been bounded by laboratory experiments.

This paper is organized as follows. Section 2 discusses the Lorentz violation coefficients relevant for α -particles and how these are related to the coefficients for the constituent protons and neutrons. Then Section 3 shows how these coefficients could impact the physical process of α -decay. In Section 4 we look quantitatively at how α -decay studies could be used to place bounds on a number of Lorentz violation coefficients and in Section 5 present our conclusions.

2 Lorentz Violation for α -Particles

In this section, we shall derive the effective Hamiltonian for an α -particle, including the effects of Lorentz symmetry violations in the proton and neutron sectors. In both this section and the next, some approximations will be necessary in order to calculate the effects of the Lorentz violation on α -decays. However, the results will be at least semi-quantitative and good enough to place order of magnitude bounds.

The minimal SME Lagrange density of a single species of fermion is

$$\mathcal{L}_f = \bar{\psi}(i\Gamma^\mu\partial_\mu - M)\psi, \quad (1)$$

where

$$M = m + \not{a} - \not{b}\gamma_5 + \frac{1}{2}H^{\mu\nu}\sigma_{\mu\nu} + im_5\gamma_5, \quad (2)$$

and

$$\Gamma^\mu = \gamma^\mu + c^{\nu\mu}\gamma_\nu - d^{\nu\mu}\gamma_\nu\gamma_5 + e^\mu + if^\mu\gamma_5 + \frac{1}{2}g^{\lambda\nu\mu}\sigma_{\lambda\nu}. \quad (3)$$

Electromagnetic interactions are introduced via the minimal coupling substitution $p^\mu \rightarrow p^\mu - qA^\mu$, where q is the charge. A nonrelativistic Hamiltonian H_f may be derived from (1) using a Foldy-Wouthuysen transformation [47]; this effective Hamiltonian is [48]

$$\begin{aligned}
H_f = & \frac{p^2}{2m} + \left[m \left(-c_{jk} - \frac{1}{2}c_{00}\delta_{jk} \right) \right] \frac{p_j p_k}{m^2} \\
& + \left[\left(-b_j + md_{j0} - \frac{1}{2}m\epsilon_{jkl}g_{kl0} + \frac{1}{2}\epsilon_{jkl}H_{kl} \right) \sigma^j - a_j - m(c_{0j} + c_{j0}) + me_j \right] \frac{p_j}{m} \\
& - \left[b_0\delta_{jk} - m(d_{kj} + d_{00}\delta_{jk}) - m\epsilon_{klm} \left(\frac{1}{2}g_{mlj} + g_{m00}\delta_{jl} \right) - \epsilon_{jkl}H_{l0} \right] \frac{p_j \sigma^k}{m} \\
& + \left\{ \left[m(d_{0j} + d_{j0}) - \frac{1}{2} \left(b_j + md_{j0} + \frac{1}{2}m\epsilon_{jmn}g_{mn0} + \frac{1}{2}\epsilon_{jmn}H_{mn} \right) \right] \delta_{kl} \right. \\
& \left. + \frac{1}{2} \left(b_l + \frac{1}{2}m\epsilon_{lmn}g_{mn0} \right) \delta_{jk} - m\epsilon_{jlm}(g_{m0k} + g_{mk0}) \right\} \frac{p_j p_k \sigma^l}{m^2}. \tag{4}
\end{aligned}$$

This is the free nonrelativistic SME Hamiltonian for a single proton or neutron, to leading order in the SME coefficients.

Many of the terms in (4) will not contribute when two protons and two neutrons are combined to form an α -particle. The effective Hamiltonian for the composite particle, H_α , involves a sum of four H_f Hamiltonians—one for each of the nucleon constituents—plus additional contributions due to nuclear binding effects. We shall not consider the binding in detail; it's role will simply be to ensure that the four nucleons follow essentially identical spacetime trajectories. Moreover, to an excellent approximation, the two protons and two neutrons in this nucleus are each separately in a spin singlet state.

So the operator to create an α -particle at $\vec{x}$ is $a^\dagger(\vec{x}) = 2b_{p\uparrow}^\dagger(\vec{x})b_{p\downarrow}^\dagger(\vec{x})b_{n\uparrow}^\dagger(\vec{x})b_{n\downarrow}^\dagger(\vec{x})$, where $b_{p\uparrow}^\dagger$ (or $b_{n\downarrow}^\dagger$) is the creation operator for a spin up proton (or spin down neutron). Because of the anticommutivity of the fermion operators,

$$b_\uparrow^\dagger(\vec{x})b_\downarrow^\dagger(\vec{x}) = \frac{1}{2} \left[b_\uparrow^\dagger(\vec{x}_1)b_\downarrow^\dagger(\vec{x}_2) - b_\uparrow^\dagger(\vec{x}_2)b_\downarrow^\dagger(\vec{x}_1) \right] \Big|_{\vec{x}_1=\vec{x}_2=\vec{x}}, \tag{5}$$

and $a^\dagger$ produces an excitation with the total proton spin and total neutron spin both equal to zero.

Each of the two protons carries the same mechanical momentum and likewise for the two neutrons. (Since the proton and neutron masses are very similar, each nucleon carries approximately one-fourth of the total momentum of the α -particle.) Consequently, when the spin-dependent terms in each H_f are added together, they give contributions to H_α which depend only on $\vec{\sigma}_{p1} + \vec{\sigma}_{p2}$ and $\vec{\sigma}_{n1} + \vec{\sigma}_{n2}$ —the total proton and neutron spin vectors in the nucleus. But in the spin-0 singlet state, both of these operators vanish identically. Therefore, none of the spin dependent terms in H_f will contribute to H_α .

So we may neglect all spin-dependent terms in H_f . Doing this, we are left with a Hamiltonian equivalent to

$$H_f \simeq \frac{p^2}{2m} - \left(c_{jk} + \frac{1}{2} c_{00} \delta_{jk} \right) \frac{p_j p_k}{m} - [a_j + m(c_{0j} + c_{j0}) - m e_j] \frac{p_j}{m}. \quad (6)$$

However, it is known that the a^μ parameters are unobservable, except in interactions that involve gravitation or flavor changing interactions [49]. The field redefinition

$$\psi \rightarrow e^{-ia \cdot x} \psi, \quad \bar{\psi} \rightarrow e^{ia \cdot x} \bar{\psi} \quad (7)$$

eliminates a from the Lagrangian (1) entirely. This is equivalent to a translation in momentum space, $p^\mu \rightarrow p^\mu - a^\mu$. In a theory with a only, the shifted $\vec{p}$ is the correct mechanical momentum $\gamma m \vec{v}$; including a in the action merely corresponds to a poor choice of canonical momentum. Since neither gravity nor the weak interaction are involved with α -decay, a will not contribute to any observable quantity in this kind of decay process. Moreover, any coefficients that enter in the same manner as a must also prove unobservable; the whole expression $[a_j - m(c_{0j} + c_{j0}) - m e_j] \frac{p_j}{m}$ cannot affect α -decay physics. Neglecting this term, we are left with the final fermion Hamiltonian relevant to α -decay,

$$H_f \simeq \frac{p^2}{2m} - [c_{(jk)} + c_{00} \delta_{jk}] \frac{p_j p_k}{2m}, \quad (8)$$

where $c_{(jk)} = c_{jk} + c_{kj}$. Only the c terms in the fermion sector can affect α -decays, and the remaining terms in the effective Hamiltonian are all separately invariant under C, P, and T.

The c_{00} term is not observable in solely nonrelativistic experiments; it merely changes the effective value of m . However, we shall retain it, and its effects can be observed by comparing the kinetic energy of a nonrelativistically moving particle with the mass energy m observed in particle creation or annihilation processes.

To find a useful effective Hamiltonian for the α -particle, we must take the sum of four H_f terms and then perform a canonical transformation. The transformation will separate the center of mass motion from the relative motions of the four nucleons, and it is the center of mass motion that determines the motion of the α -particle.

To see how the center of mass Hamiltonian is modified by c -type Lorentz violation for the constituents, it is simpler to first consider the case of a two-particle bound state. The problem can be further simplified by considering a situation in which there is Lorentz violation in the Hamiltonian for only one of the two constituents. Once this simple example has been worked out, the generalization to more constituent particles and more sources of Lorentz violation is straightforward.

For the two-particle example, the Hamiltonian is

$$H = \frac{p_1^2}{2m_1} + \frac{p_2^2}{2m_2} - [c_{(jk)} + c_{00} \delta_{jk}] \frac{p_{2j} p_{2k}}{2m_2}. \quad (9)$$

Since the term in brackets in (9) is symmetric in (jk) and represents a small correction, we may diagonalize it by a rotation, choosing spatial coordinates in which the kinetic energy for particle 2 has no off-diagonal $p_j p_k$ terms. In these coordinates, the kinetic energy splits, as it conventionally does, into three pieces, each of the form

$$H_j = \frac{p_{1j}^2}{2m_1} + [1 - c_{(jj)} - c_{00}] \frac{p_{2j}^2}{2m_2}. \quad (10)$$

In (10) and for the remainder of this paragraph, j represents a specific coordinate and is not to be summed over. H_j describes one-dimensional dynamics equivalent to those for two particles of masses m_1 and $m'_2 = m_2/[1 - c_{(jj)} - c_{00}]$. The effective center of mass coordinate is $R_j = \frac{m_1 r_{1j} + m'_2 r_{2j}}{m_1 + m'_2}$, and the conjugate momentum is the total momentum $P_j = p_{1j} + p_{2j}$. The center of mass part of the Hamiltonian then becomes $P_j^2/2(m_1 + m'_2)$.

Including the dynamics in all three directions, the total center of mass Hamiltonian is therefore

$$H_{CM} = \frac{1}{2(m_1 + m_2)} \left\{ \delta_{jk} - \frac{m_2}{m_1 + m_2} [c_{(jk)} + c_{00} \delta_{jk}] \right\} P_j P_k \quad (11)$$

(once again summing over j). The results of the previous paragraph dictate this formula holds in coordinates for which $c_{(jk)}$ is diagonal; and since (11) is written in a tensor form, it must also hold in the original, unrotated coordinate system.

The generalization to more Lorentz-violating particles is straightforward. The center of mass Hamiltonian will contain a mass-weighted sum of the Lorentz violation coefficients for the constituents. The weights represent the fraction of the momentum carried by various constituents, and the sum is the effective Lorentz violation coefficient for the composite particle. For the α -particle, we find

$$H_\alpha = \frac{1}{4(m_p + m_n)} \left\{ \delta_{jk} - \frac{m_p}{m_p + m_n} [c_{(jk)}^p + c_{00}^p \delta_{jk}] - \frac{m_n}{m_p + m_n} [c_{(jk)}^n + c_{00}^n \delta_{jk}] \right\} P_j P_k. \quad (12)$$

This does not yet include the effects of nuclear binding. As a first approximation, we may treat the binding energy $-\epsilon = m_\alpha - 2m_p - 2m_n$ as if it were divided up equally among the four constituent hadrons. This means replacing m_p and m_n in H_α with $m_p - \epsilon/4$ and $m_n - \epsilon/4$, respectively. If we also neglect the neutron-proton mass difference, the effective Hamiltonian for a free α -particle becomes

$$H_\alpha = \frac{1}{2m_\alpha} \left(\delta_{jk} - \frac{1}{2} k_{jk}^\alpha \right) P_j P_k, \quad (13)$$

with $k_{jk}^\alpha = c_{jk}^p + c_{jk}^n + (c_{00}^p + c_{00}^n) \delta_{jk}$.

The k_{jk}^α coefficients are nonrelativistic versions of the Lorentz violation coefficients $k_{\mu\nu}$ for a scalar field. In the presence of $k_{\mu\nu}$, the Lagrange density for a free relativistic scalar is

$$\mathcal{L}_\phi = \frac{1}{2} (\partial^\mu \phi) (\partial_\mu \phi) + \frac{1}{2} k_{\mu\nu} (\partial^\nu \phi) (\partial^\mu \phi) - \frac{m^2}{2} \phi^2. \quad (14)$$

However, the coefficients k_{0j} or k_{00} are intrinsically relativistic. They control violations of boost invariance, and they cannot be measured in a purely nonrelativistic experiment. Yet the relationship between c_{jk}^n , c_{jk}^p , and k_{jk}^α must be the same in every Lorentz frame, since we may always repeat the preceding analysis with an α -particle that is moving nonrelativistically in the desired frame. In order for this to hold, the full effective Lorentz violation coefficient for the α -particle must be $k_{\mu\nu}^\alpha = c_{\nu\mu}^p + c_{\nu\mu}^n$. (The change in the placement of c_{00} terms just corresponds to a change in the overall normalization of the field and has no physical meaning.) For a more general spin-0 bound state, the coefficient $k_{\mu\nu}$ will be a mass-weighted sum of the constituents' $c_{\nu\mu}$ coefficients, like the one appearing in (12).

When each nucleon is minimally coupled to the electromagnetic field by the replacement $\vec{p} \rightarrow \vec{p} - q\vec{A}$ and $H_f \rightarrow H_f - qA_0$, the total momentum and α -particle Hamiltonian transform as $\vec{P} \rightarrow \vec{P} + 2e\vec{A}$ and $H_\alpha \rightarrow H_\alpha + 2eA_0$, where $e = -|e|$ is the charge of the electron. For nonrelativistic motion in the absence of an external magnetic field, the contribution of the vector potential $\vec{A}$ may be neglected. There can also be interactions between the α -particle and a strong interaction potential V_s ; when included, this gives the final interacting Hamiltonian

$$H_\alpha = \frac{1}{2m_\alpha} \left(\delta_{jk} - \frac{1}{2}k_{jk}^\alpha \right) P_j P_k + 2eA_0(\vec{x}) + V_s(\vec{x}). \quad (15)$$

3 Calculating α -Decay Rates

We shall now proceed to a calculation of how Lorentz violation could impact the α -decay of a nucleus. There are three major places in which Lorentz violation can enter the decay process. These can be loosely related to three constituents of the interaction: the attractive interaction in the parent nucleus, the expelled α -particle, and the electromagnetic interaction between the α -particle and the daughter nucleus.

The decay process can be understood as the α -particle tunneling from the deep attractive potential well of the nucleus, through the Coulomb barrier, and escaping to infinity. When the α -particle energy is small compared with the height of the barrier, the details of the potential inside the nucleus are fairly unimportant. We shall therefore neglect the effects of Lorentz violations on the nuclear potential. In fact, if the Lorentz violations in various sectors of the SME are comparable in magnitude (as naturalness conditions would suggest), the dominant Lorentz-violating contribution to the decay rate Γ will arise from one particular factor in our calculation. The exponential part of the barrier penetration factor depends much more strongly on the Lorentz violation parameters than any other element in the formula for Γ ; and the stronger dependence of this factor on k^α is most pronounced when the energy of the decay is smallest compared with the height and width of the Coulomb barrier.

We shall examine the various factors that together compose the decay rate below.

However, we must first discuss the question of Lorentz violation in the electromagnetic sector, since electromagnetic Lorentz violation effects do not become negligible compared with the effects of k^α in any kinematical limit. There is one form of spin-independent Lorentz violation like c or k^α for each particle species in the standard model. Consideration only of spin-independent forms is justified by a combination of factors. Since the α -particle has no spin angular momentum, it is automatic that any Lorentz violations in its sector must be spin independent. This straightforward general argument was confirmed by the calculations in Section 2. In contrast, the electromagnetic sector of the SME certainly contains terms that depend on photon polarization. However, these terms are extremely tightly constrained by astrophysical polarimetry [38, 39, 40]. Any polarization dependence in the phase speed of light will lead to birefringence—a change in the polarization of light waves as they propagate. Birefringence with the right energy dependence to indicate Lorentz violation is not observed even in radiation that has traversed cosmological distances. Therefore it is reasonable to neglect these terms in the action, leaving behind an electromagnetic sector that is spin independent. With only the conventional terms and spin-independent Lorentz violation, the Lagrange density for the free electromagnetic sector is

$$\mathcal{L}_A = -\frac{1}{4}F^{\mu\nu}F_{\mu\nu} - \frac{1}{4}(k_F)^\beta{}_{\mu\beta\nu}(F^{\rho\mu}F_\rho{}^\nu + F^{\mu\rho}F^\nu{}_\rho). \quad (16)$$

The relevant type of Lorentz violation in each sector can be parameterized by a two-index symmetric tensor. However, only the differences between these tensors are observable physically. A coordinate transformation can be used to eliminate this kind of Lorentz violation entirely from one sector, at the cost of changing the coefficients in all other sectors. Specifically, once the birefringent terms in the electromagnetic sector are set to zero, the entire sector may be made conventional by a coordinate redefinition $x^\mu \rightarrow x^\mu - \frac{1}{2}(k_F)^{\beta\mu}{}_{\beta\nu}x^\nu$. Under such a redefinition, the Lorentz violation in the α -particle sector transforms $k_{\mu\nu}^\alpha \rightarrow k_{\mu\nu}^\alpha - (k_F)^\beta{}_{\mu\beta\nu}$. It is this difference of coefficients that is ultimately measurable; however, for notational simplicity, we shall henceforth assume $(k_F)^\beta{}_{\mu\beta\nu} = 0$.

Now we can discuss the details of the α -decay process in the presence of k^α . There are two ways of treating the tunneling process by which the α -particle escapes through the electrostatic potential of the nucleus. The tunneling rate may be determined using either the properties of exact Coulomb wave functions or the Wentzel-Kramers-Brillouin-Jeffreys (WKBJ) approximation. In generalizing the analysis of α -decay to cover the possibility of Lorentz violation, we shall opt for the latter approach.

However, this approach immediately runs into a problem. In the presence of k^α , the modified Schrödinger is no longer separable (in either spherical or parabolic coordinates). In order to use the WKBJ approximation, it is generally necessary to separate the variables; the WKBJ technique can then be applied to one variable at a time. So in order to get around this difficulty, we must introduce another approximation.

The new approximation is a form of the eikonal approximation. The conventional eikonal approximation, when applied to scattering problems, proceeds as follows. One examines the linear path that a particle of a given impact parameter would follow in the absence of interactions. When the interaction is “turned on,” a particle moving along this line would acquire a phase shift—which is just the time integral of the scattering potential along the straight trajectory. The scattering amplitude can then be calculated from this phase shift.

In the case of α -decay, a different sort of eikonal approximation is required. To calculate the barrier penetration factor, we shall treat the ejected α -particle as if it were escaping along a well-defined linear path in the direction of its ultimate velocity. However, since the region of interest along this path is part of the classically forbidden region, we shall not be calculating a phase accrued along the path; instead we shall calculate the exponential suppression of the wave function along the straight line. This reduces the three-dimensional problem to a one-dimensional problem for the motion in the direction $\hat{v}$ of the velocity. The kinetic term in the α -particle Hamiltonian for the motion along this axis is

$$K_{\hat{v}} = \frac{1}{2m_{\alpha}} \left(1 - \frac{1}{2} k_{jk}^{\alpha} \hat{v}_j \hat{v}_k \right) P^2, \quad (17)$$

where P is now the one-dimensional momentum in the relevant direction. [Actually, in the presence of the Lorentz violation, the directions of the momentum and the velocity generally differ; the velocity is $v_k = \frac{1}{m_{\alpha}}(p_k - \frac{1}{2}k_{jk}^{\alpha}p_j)$. However, the difference between the two directions only contributes a higher order correction to the penetration factor.] For motion purely in the $\hat{v}$ -direction, the effect of the Lorentz violation is to modify the inertial mass of the α -particle to $m_{\alpha} \left(1 + \frac{1}{2}k_{jk}^{\alpha} \hat{v}_j \hat{v}_k \right)$.

Note that this use of the eikonal approximation is only straightforward if the nucleus and the α -particle are in a relative S state. However, the barrier penetration factors for $L = 0$ angular momentum states are always greater than for higher angular momentum states at the same energy, because for $L > 0$ states there is an additional centrifugal term in the effective potential. Because of this (and because of the related fact that the wave function for two particles with relative angular momentum $L > 0$ vanishes when the particles’ positions coincide), S states frequently dominate in nuclear interaction processes, and we shall consider only S-wave α -decays in our calculations.

Applying the standard WKB technique, the barrier penetration factor is then

$$T = \beta^2 \exp \left[-2\sqrt{2m_{\alpha}} \left(1 + \frac{1}{4}k_{jk}^{\alpha} \hat{v}_j \hat{v}_k \right) \int_{r_N}^{r_E} dr \sqrt{2(Z-2)e^2/4\pi r - E} \right], \quad (18)$$

where r_N and $r_E = (Z-2)e^2/2\pi E$ are the classical turning points. r_N represents the nuclear radius, at which the attractive nuclear potential binding the α -particle to the nucleus comes into play; for a nucleus containing A nucleons, $r_N \approx 1.4A^{1/3}$ fm. The escape radius r_E is the beginning of the classically allowed region outside the repulsive Coulomb potential. The prefactor β^2 would be negligible for a sufficiently slowly varying

potential; while the exponential arises from the lowest order term in an expansion in powers of $\hbar$, β comes from a higher order term. However, the higher order correction becomes relevant in the region where the dominant potential changes rapidly from being the repulsive Coulomb to the attractive nuclear interaction; taking it into account, we find $\beta^2 = \sqrt{(r_E/r_N) - 1}$.

The integral in the exponent gives

$$\int dr \sqrt{\frac{1}{r} - \frac{1}{r_E}} = r \sqrt{\frac{1}{r} - \frac{1}{r_E}} + \frac{1}{2} \sqrt{r_E} \tan^{-1} \left[\frac{2r - r_E}{2\sqrt{r(r_E - r)}} \right]. \quad (19)$$

When E is small compared with the characteristic potential at the nucleus, $(Z-2)e^2/2\pi r_N$, the lower limit of integration becomes relatively unimportant. This limit is equivalent to having $r_E \gg r_N$, so that the width of the barrier region is large compared with the size of the nucleus. The fact that the dependence on r_N in this limit is weak is fortuitous, since the relevant nuclear size can only be determined approximately (and might itself be affected by Lorentz violation). In the $r_E \gg r_N$ regime, it is a reasonable approximation to set $r_N \approx 0$. (However, the finite size of the nucleus is an important effect in real α -decays. Some of the earliest measurements of the size of certain α -emitting nuclei were actually based on analyses of the finite nuclear size corrections to the decay rate.)

In the energy regime for which the penetration factor is relatively insensitive to the precise value of r_N , any Lorentz violation effects in the strong force that holds the parent nucleus together are of lesser importance. The most crucial feature of the penetration factor T is that it depends on k^α as

$$T = \beta^2 \left(\frac{T_0}{\beta^2} \right)^{(1 + \frac{1}{4} k_{jk}^\alpha \hat{v}_j \hat{v}_k)}, \quad (20)$$

where $\beta^2 T_0$ is the penetration factor in the absence of k^α Lorentz violation. T depends exponentially on k^α ; the smaller the penetration factor is, the larger the fractional dependence on the Lorentz violation will be.

Taking the $r_N \approx 0$ limit in the exponent, the penetration factor becomes

$$T = \beta^2 \exp \left[-2 \sqrt{\frac{m_\alpha (Z-2) e^2}{\pi}} \left(1 + \frac{1}{4} k_{jk}^\alpha \hat{v}_j \hat{v}_k \right) \left(\frac{\pi}{2} \sqrt{r_E} \right) \right] \quad (21)$$

$$= \beta^2 \exp \left[-(Z-2) e^2 \sqrt{\frac{m_\alpha}{2E}} \left(1 + \frac{1}{4} k_{jk}^\alpha \hat{v}_j \hat{v}_k \right) \right], \quad (22)$$

with the well-known dependence on $\exp(-bE^{-1/2})$. The leading corrections to the exponential for finite r_N are

$$T = \beta^2 \exp \left\{ -bE^{-1/2} \left[1 - \frac{4}{\pi} \left(\frac{r_N}{r_E} \right)^{1/2} + \frac{2}{3\pi} \left(\frac{r_N}{r_E} \right)^{3/2} \right] \right\}. \quad (23)$$

The full decay rate is $\Gamma = \frac{\omega}{2\pi}T$, where $\frac{\omega}{2\pi}$ is the frequency for oscillations of the α -particle inside the attractive nuclear potential region. The frequency gives the rate at which the α -particle strikes the inside of the Coulomb barrier, and T is the probability that it tunnels through and escapes during a single collision. An estimate of ω is $\omega \sim \frac{1}{r_N} \sqrt{\frac{E}{m_\alpha}}$; this is approximately the inverse of the time which a particle with kinetic energy E and mass m_α takes to traverse a distance r_N .

Neither β nor ω depend exponentially on the Lorentz violation coefficients. We therefore expect the dominant contribution of the Lorentz violation to be made through its effects on the exponential in T . Neglecting the Lorentz violation in the prefactor $\beta^2\omega$, the decay rate may be written in the simplified form

$$\Gamma = \Gamma_0 \exp \left(-\frac{(Z-2)e^2}{4} \sqrt{\frac{m_\alpha}{2E}} k_{jk}^\alpha \hat{v}_j \hat{v}_k \right), \quad (24)$$

where Γ_0 is the rate in the absence of Lorentz violation. In evaluating Γ_0 , many of the approximations (such as $r_N \approx 0$) that were used in our determination of the Lorentz-violating correction are not necessary. In fact, Γ_0 does not need to be calculated at all; it can be taken from experimental data.

4 Comparison with Experiment

What (24) predicts is an anisotropy in the emission of the α -particles. The decay rate depends on the emission direction $\hat{v}$. Presuming the anisotropy is a small correction,

$$\Gamma = \Gamma_0 \left(1 - \frac{(Z-2)e^2}{4} \sqrt{\frac{m_\alpha}{2E}} k_{jk}^\alpha \hat{v}_j \hat{v}_k \right). \quad (25)$$

The effects of Lorentz violation are enhanced by the potentially large parameter

$$\frac{(Z-2)e^2}{4} \sqrt{\frac{m_\alpha}{2E}} = 0.99(Z-2) \left(\frac{E}{1 \text{ MeV}} \right)^{-1/2}. \quad (26)$$

To detect an anisotropy, the fractional difference between the decay rates in different directions must be greater than the fractional error in the measured rate due to random errors. If N counts are collected, the signal to noise ratio goes as $\sqrt{N}$, and repeated measurements made on the same isotope can produce bounds on k^α that scale as $N^{-1/2}$.

To measure an anisotropy in Γ is, in principle, straightforward. A sample of decaying material should be placed inside a detector that would identify the directions of any outgoing α -particles. This directional data would be used to search for evidence of anisotropy. Of course, in a laboratory located on the Earth, the planet's rotation must be accounted for in any absolute directional measurement. The direction of each decay in the laboratory

coordinates must be re-expressed in a non-rotating coordinate system. There is a particular sun-centered celestial equatorial coordinate system of this nature, in which bounds on Lorentz-violating coefficients are conventionally expressed. The conversion between laboratory and sun-centered coordinates is obviously dependent on the sidereal time, and so the time associated with each decay event must be recorded along with its direction. Details of the sun-centered coordinates are given in [50].

In practice, the kind of experiment described here could be tricky. For example, it is desirable to have a small physical sample, so that rescattering of α -particles produced by decays well inside the sample could be minimized. The ideal α -emitter for these purposes is one whose half-life is well known, which has only one major decay mode, and which has nuclear spin $I = 0$ and decays into another $I = 0$ nucleus. The spin condition is important for two reasons. First, having both the parent and daughter nuclei spinless (as well as the α -particle) ensures that the decay proceeds via an S-wave tunneling state. Second, if the decaying isotope had a nonzero spin, then a slight polarization of the population of parent nuclei could lead to a small anisotropy in the decay rate, which could depend on the relative orientations of the net nuclear spin and the outgoing α -particles' trajectories.

A nuclide with the desired properties is ^{222}Rn [51]. Its half-life of 3.8235 days is known with a fractional 1σ error of less than 10^{-4} . ^{222}Rn is an $I^P = 0^+$ state, which decays overwhelmingly to ^{218}Po , another 0^+ isotope. The decay energy is 5.5903 ± 0.0003 MeV.

If any anisotropy in the α -decay of ^{222}Rn can be ruled out with the same $\lesssim 10^{-4}$ accuracy with which the total half-life is known, (25) and (26) dictate that the Lorentz violation coefficients k^α may be bounded at the level $|k_{jk}^\alpha| \lesssim 2 \times 10^{-6}$ (although the trace k_{jj}^α would not be constrained, since it does not lead to any anisotropy). These bounds are not very strong, especially compared with the results of atomic clock experiments, but they could give new constraints on neutron and proton c coefficients that have not been bounded in the laboratory.

The reason that an experiment like this would be sensitive to new coefficients is that the α -decay experiment would involve the measurement of actual decay directions. The extremely precise clock comparison experiments instead measure energy shifts. The energy of certain transitions can vary as the angle between the laboratory magnetic field and a background vector field changes. However, not all possible magnetic field directions are sampled as the Earth rotates, which is why certain coefficients are not measured. Constraints on the various coefficients which are difficult to measure in clock tests can come from cosmic ray observations, because cosmic rays coming from all possible directions can potentially be observed [52]. However, these astrophysical bounds lack the certainty associated with controlled laboratory measurements.

5 Conclusion

In this paper, we have examined Lorentz violation for composite particles, specifically α -particles. In low-energy physics, Lorentz violation can enter the in the α -particle sector only through the coefficients $k_{\mu\nu}^\alpha$. These coefficients are linear combinations of the proton and neutron coefficients $c_{\nu\mu}^p$ and $c_{\nu\mu}^n$. In the limit of exact isospin symmetry, $k_{\mu\nu}^\alpha = c_{\nu\mu}^p + c_{\nu\mu}^n$.

More generally, the coefficients for the Lorentz-violating, spin-independent modification of a composite particle's nonrelativistic kinetic energy are linear combinations of the analogous coefficients for its constituent particles. The weight given to each coefficient in this sum is determined by the fraction of the total momentum that is carried by the corresponding constituent. This is the solution to a simple instance of the more general problem of determining the Lorentz violation coefficients for a composite particle in terms of the coefficients for the constituents.

The example of the α -particle is especially straightforward, because it is a spin singlet composed of four extremely similar particles. It would be desirable to get an equivalent understanding of more complicated nuclei. This would be particularly useful for improving the bounds on Lorentz violation that come from clock comparison experiments. Such bounds are currently evaluated using extremely crude models of the nucleus. The scope and accuracy of the resulting bounds would be significantly improved with a better understanding of the relationship between the SME coefficients for nucleons and the hyperfine transition frequencies that can actually be observed in the laboratory.

Even trickier than the problem of relating the effective Lorentz violation coefficients for nuclei to the coefficients for their hadronic constituents is that of relating the proton, neutron, and other hadron coefficients to the coefficients for the underlying quark and gluon fields. These constituents interact strongly through quantum chromodynamics, and the interaction cannot be treated as a small correction. Renormalization group effects are also very important; the ultimate relationship between the Lorentz violation coefficients for the physical hadrons and the coefficients for the parton fields will depend sensitively on the renormalization scale. The whole problem is quite difficult; however, the subject is also extremely interesting, and it represents one of the most important open problems concerning the structure of the SME.

This paper also examined another phenomenon in quantum mechanics whose interaction with Lorentz violation has been very little studied: tunneling. In reactions, such as α -decay, whose rate is principally determined by a quantum barrier penetration factor T , the sensitivity to Lorentz-violating effects may be enhanced. This is a consequence of the penetration factor's exponential dependence on various parameters. If Lorentz violation leads to a small increase in the height of the potential barrier through which a particle must tunnel, the tunneling rate will be diminished by an exponentially greater amount.

While an experiment searching for a possible anisotropy in the emission of α -particles by a decaying isotope is interesting, the bounds that such an experiment might place on physical Lorentz violation coefficients are not very precise. Such an experiment would be

sensitive to certain coefficients that have not previously been constrained by laboratory experiments; however, the coefficients in question have been bounded at the 5×10^{-14} level by observations of ultra-high-energy cosmic rays. Constraints based on controlled laboratory experiments are generally preferable to bounds based on inferences drawn from astrophysical data, but it is unfortunate that the laboratory tests proposed here might only give bounds at the 2×10^{-6} level.

However, this work opens the door to the possibility of constraining Lorentz violation with other experiments involving tunneling. The ideal experiment for placing such constraints would have a high barrier, which would make the tunneling rate more sensitive to any Lorentz violations. To compensate for the low tunneling rate, a large flux of particles against the barrier would be required. If a process with the desired characteristics is found, it could be used to place new bounds on coefficients for Lorentz violation.
